Class #9

Prof. Nathan Taback

2018-11-12

Today's Class

- Supervised versus Unsupervised Learning
- Classification Trees
- Interpreting a Classification Tree
- Geometric Interpretation of a Classification Trees
- Classification Tree Methodology
- Training and Testing Classification Trees
- Accuracy of Classification Trees
- ROC Curves

Learning from Data

Supervised versus Unsupervised Learning

- Many statistical learning problems fall into one of two categories: supervised or unsupervised.
- In supervised learning problems there is a response measurement y that we would like to **predict**, based on variables $x_1, x_2, ..., x_p$.
- Variables are often called features, predictors, covariates, independent variables, or inputs.
- Response measurements are often called outputs, labels, or dependent variables.

Image Classification Example

- Imagine that we want to build a system that can classify images as containing, say, a house, a car, a person or a pet.
- We first collect a large data set of images of houses, cars, people and pets, each labelled with its category.
- Convert the images to input variables.

```
library(jpeg)
# get RGB intensity 0 - 255
img <- readJPEG("pika.jpg")
img[40:41,51:52,1]</pre>
```

```
## [,1] [,2]
## [1,] 0.1568627 0.015686275
## [2,] 0.2745098 0.003921569
```

Image Classification Example

- "Train" an algorithm.
- The algorithm produces an output in the form of a vector of scores, one for each category.
- We want the desired category to have the highest score of all categories, but this is unlikely to happen before training.
- We next compute the error between the output scores and the true scores.

Classification Trees

Classification Trees

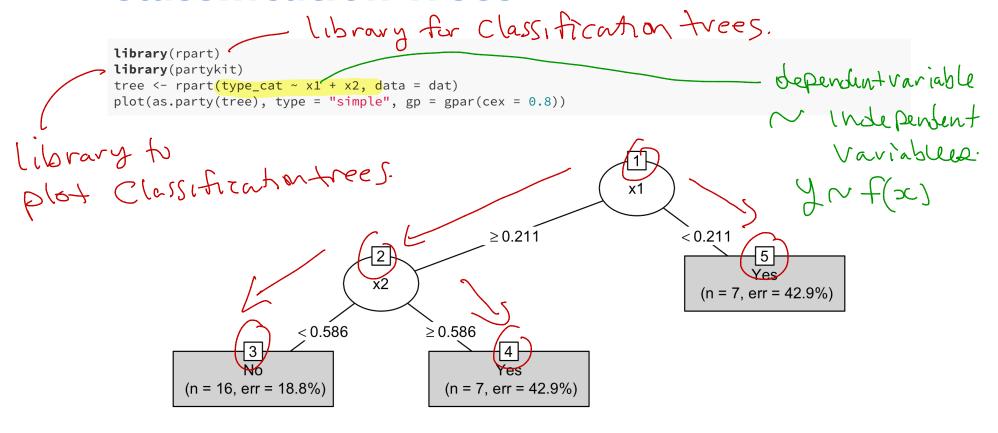

- Data was collected on 50 cancer patients to investigate the effectivness (Yes/No) of a treatment.
- Two quantitative variables, $x_i \in (0,1), i = 1, 2$, are considered to be important predictors of effectiveness.

 J= { Yes W + reatment worked }

 No W + treatment bailed

Classification Trees

nodes.

Why is terminal node 5 prediction = Yes. ?

Interpreting a Classification Tree

prediction is based on

majority rule. (n = 7, err = 42.9%)

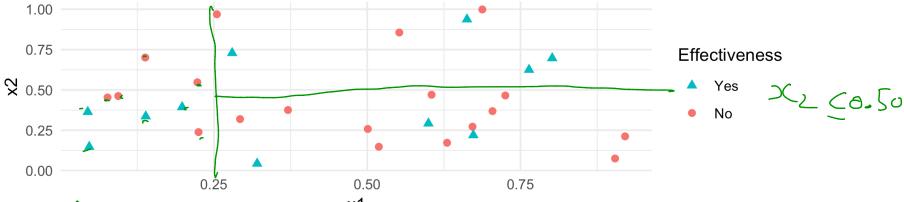

- This classification tree has five nodes, and three of these nodes are terminal nodes.
- Terminal nodes are indicated by rectangular boxes, and nonterminal nodes are indicated by ovals.

- If a subject has x1 < 0.211 then the prediction is that effectiveness = Yes (i.e., the treatment is effective). 7 subjects have x1 < 0.211 and 42.9% (3 subjects) have effectiveness = No, and 57.1% (4 subjects) have effectiveness = Yes.
- If a subject has $x1 \ge 0.211$ and x2 < 0.586 then the prediction is that effectiveness = No. 16 subjects have $x1 \ge 0.211$ and x2 < 0.586 and 18.8% (3 subjects) have effectiveness = Yes, and 81.2% (13 subjects) have effectiveness = No.

Geometric Interpretation of a Classification Trees

A scatter plot of x_1, x_2 is shown below where each point is labelled by effectivness.

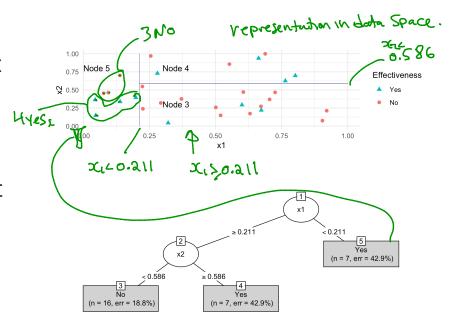

```
ggplot(dat, aes(x1, x2, shape = factor(type_cat), colour = factor(type_cat))) +
  geom_point(size = 2) +
  theme_minimal() +
  scale_color_discrete(name = "Effectiveness", breaks = c("Yes", "No")) +
  scale_shape_discrete(name = "Effectiveness", breaks = c("Yes", "No"))
```

NO x1 5 Nos 2120.25 4 Yess.

Geometric Interpretation of a Classification Tree

- An equivalent way of looking at this tree is that it divides the unit square into rectangles.
- The division is recursive since it first splits the rectangle into two pieces, then it may split each of these rectangles into two pieces, etc.

Classification Tree Methodology

- 1. A set of binary questions. For example, is $\{x1 < 0.5\}$?
- 2. A method to evaluate if a split is "good".
- 3. A rule to stop-splitting.
- 4. A rule for assigning every terminal node to a category (i.e., Yes or No).

Classification Tree Methodology - The standard set of questions

M=2 in Cancer example.

- Suppose that we have M variables $x_1, x_2, ..., x_M$ which can be a mixture of of continuous and categorical variables.
- Each split depends on the value of only a single variable.
- For each continuous variable x_m , a split is of the form: is $\{x_m \leq c\}$? or is $\{x_m > c\}$?, $c \in (-\infty, \infty)$.
- If x_m is categorical, taking values, say, in $\{b_1, b_2, \dots, b_L\}$ then splits are of the form: is $\{x_m \in S\}$? as S ranges over all subsets of $\{b_1, b_2, \dots, b_L\}$.

Classification Tree Methodology - The standard set of questions

- At each node the tree algorithm searches through the variables one by one.
- For each variable it finds the 'best' split.
- Then the algorithm compares the *M* best single variable splits and selects the best of the best.

Classification Tree Methodology - The Splitting and Stop Splitting Rule

In order to perform recursive binary splitting:

- A node of a tree is said to be *impure* when all classes are equally mixed together.
- For example, a node that had 50% of subjects with effectiveness = No and 50% of subjects with effectiveness = Yes.
- Two popular measures of impurity, i(t), for node t are Gini, and Entropy:

$$Gini(t) = 1 - (w_1(t))^2 + (w_2(t))^2, \ \ Entropy(t) = -w_1(t)\log_2(w_1(t)) + w_2(t)\log_2(w_2(t)),$$

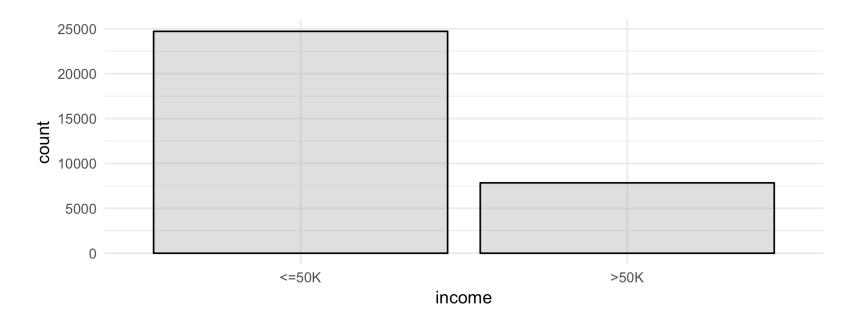

where $w_i(t)$ is the fraction of records belonging to class i at node t.

Classification Tree Methodology - The Splitting and Stop Splitting Rule

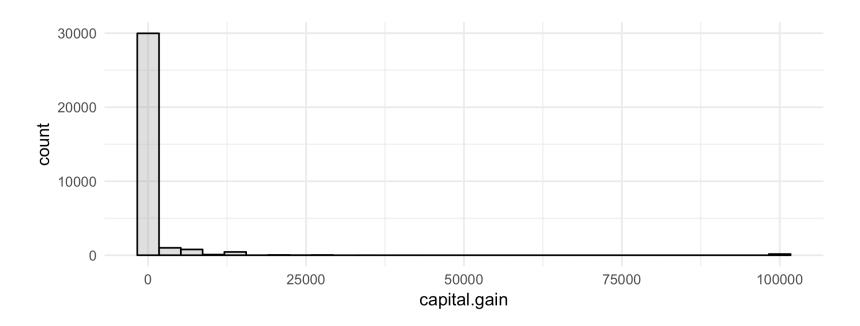

- The "goodness" of a split is the decrease in impurity ΔI . The maximum decrease in impurity is defined as the best split.
- A simple stop-splitting rule is to set a threshold, say $\beta > 0$, and declare a node terminal if $\Delta I < \beta$.

- What factors can be used to predict if a person is a high earner?
- Capital gains tax is the tax paid on profit from the sale of an asset (e.g., stock, bond, property).
- Does the amount of capital gains tax predict if a person is a higher earner?

```
census %>% ggplot(aes(income)) +
  geom_bar(colour = "black", fill = "grey", alpha = 0.5) +
  theme_minimal()
```

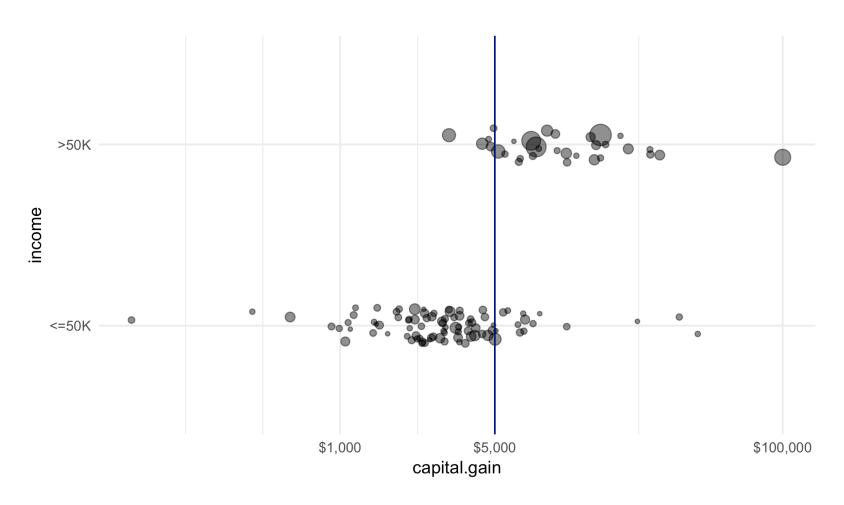

```
census %>% ggplot(aes(capital.gain)) +
  geom_histogram(colour = "black", fill = "grey", alpha = 0.5) +
  theme_minimal()
```

How Can we Minimite error when Choosing Cut-point?

```
census %>% ggplot(aes(x = capital.gain, y = income)) +
 geom_count(position = position_jitter(width = 0, height = 0.1), alpha = 0.5) +
 scale_x_{\log 10}(labels = scales::dollar, breaks = c(0,1000,5000,100000)) +
 theme minimal() +
 theme(legend.position = "none")
                                     Enlor.
   >50K
                                                                                21101.
ncome
  <=50K
                                                  $5.000
                                 $1.000
                                                                                   $100.000
                                           capital.gain
     Us Capital gains > 5,000 then income > 50 \text{ K}.
```

Classify people with capital gains less than \$5000 as low earners and greater than \$5000 as high earners.

Evaluating Classification Tree Models

Resampling Methods in Statistics

- There are several types of resampling methods in statistics.
- The randomization and permutation tests have been used to calculate p-values.
- The bootstrap has been used to calculate confidence intervals.
- Resampling can also be used to assess the accuracy of a prediction model.

Validation Set Approach

- Suppose that we would like to estimate the test error associated with fitting a particular statistical learning method on a set of observations.
- The validation set approach involves randomly dividing the available set of observations into two parts: a training set and a validation set or hold-out set.
- The tree model is fit on the training set, and the fitted model is used to predict the responses for the observations in the validation set.

Validation Set Approach

The validation set approach has two drawbacks:

- 1. The test error rate can be variable since it depends on which observations are included in the training and validation set.
- 2. Only a subset of the observations are used to fit the tree. Statistical methods perform worse when trained on fewer observations. Thus, the validation set approach may tend to overestimate the test error rate.

Training and Testing Classification Trees

- Separate the data set into two data sets by randomly selecting rows.
- A sample of 80% of the rows will become the *training* data set.
- The remaining 20% will be set aside as the *testing* (or "hold-out") data set.
- There are no formal rules about the percentage of data that should be training and testing.

Training and Testing Classification Trees

- to replicate resulti. set.seed(364) # number of observations in census data n <- nrow(census)</pre> Randon of 20% of rows ## [1] 32561 # random sample of 20% of row indexes test_idx <- sample.int(n, size = round(0.2 * n))</pre> # training data is all observations except from training row indexes train <- census[-test idx,] exclude these rows in training Set 1-es 80% of data is randomly nrow(train) # of rowsin ## [1] 26049 training Solocted. # test data test <- census[test_idx,]</pre> nrow(test) # of rows in test set. ## [1] 6512

Training and Testing Classification

Trees

```
this function ensures that income 15 treated as a factor.
train <- train %>%
  mutate(income = factor(income), workclass = factor(workclass),
         education = factor(education), marital.status = factor(marital.status),
         occupation = factor(occupation), relationship = factor(relationship),
         race = factor(race), sex = factor(sex))
test <- test %>%
  mutate(income = factor(income), workclass = factor(workclass),
         education = factor(education), marital.status = factor(marital.status),
         occupation = factor(occupation), relationship = factor(relationship),
         race = factor(race), sex = factor(sex))
```

form two data sets with all the feature variables/ Covariates.

```
train %>%
group_by(income) %>%
summarise(n = n()) %>%
mutate(relfreq = round(n/sum(n),2))

## # A tibble: 2 x 3
## income n relfreq
## <fct> <int> <dbl>
frequency.
## 1 <=50K 19732 0.76
## 2 >50K 6317 0.24

## In data Set.
```

■ If we predict that everyone in the training data earns less than 50K then we will be correct with 76% accuracy.

■ If we use the plot of income versus capital gains and we use the split \$5000 capital gains then the accuracy of our prediction changes to:

3 >50K FALSE

4 >50K TRUE

5115

1202

Example: Predicting High Earners - Confusion Matrix

The data can be displayed as a confusion matrix.

```
confusion <- matrix(confusion_dat$n,byrow = F, ncol = 2)
rownames(confusion) <- c("Cap Gains < $5000", "Cap Gains >= $5000")
colnames(confusion) <- c("Income <50K", "Income >= 50K")
confusion

## Cap Gains < $5000
## Cap Gains >= $5000

## Cap Gains >= $5000

## Cap Gains >= $5000

## Cap Gains >= $5000

***Toricle **

**Toricle **

**To
```

■ The overall accuracy has increased to (19613+1202)/(19613+1202+119+5115) = 0.799071.

80% of people are Correctly Classified Using Coop-gains Split 25000

Example: Predicting High Earners - Confusion Matrix

- Is \$5000 the "best" split of capital gains to predict income?
- We want to find the value of capital gains such that it "splits" the data into low/high income.
- There are several measures that are used to find measure the goodness of a split.
- Two popular measures are the Gini index and Entropy.

Example: Predicting High Earners - Plotting

Classification Tree Accuracy

- The test data was not used to build the tree.
- If the tree only works well on the data that was used to build the tree, and poorly on a new set of data then the model (i.e., tree) is said to be **overfit**.
- This is the rationale behind using part of the data to buid the model (i.e., tree) and using another part to test the accuracy of the tree.

If a prediction algorithmis built and works very well on the training data, but does not work well on new data then this is called over fitting.

Classification Tree Accuracy

■ The accuracy of the classification tree model is captured in a table of actual (observed) incomes versus the predicted incomes for each person.

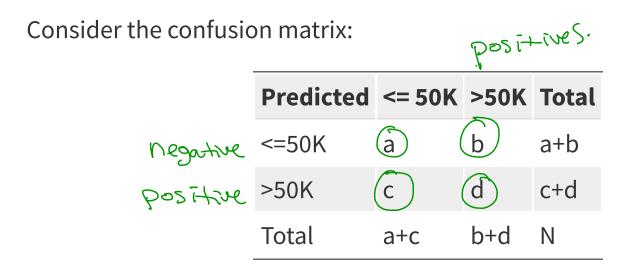

This Cutpoint leads

■ The table is often called a **confusion matrix**.

- The overall accuracy of the tree is (4969 + 294)/(4969 + 1230 + 19 +294) = 0.8082002.
- For those that earned <=50K the accuracy is: 4969/(4969 + 19) = 0.9961909.</p>
- For those that earned >50K the accuracy is: 294/(294 + 1230) = 0.1929134.

to Classifying people

Classification Tree Accuracy

$$N = (a + b + c + d).$$

Assume we are trying to predict >50K. So this outcome will be considered positive, and <=50K is negative.

- True positive rate (sensitivity): d/(b+d)
- True negative rate (specificity): a/(a+c)
- False positive rate: c/(a+c)
- False negative rate: b/(b+d)

Classification Tree Accuracy

predicted_tree <- predict(object = tree, newdata = train, type = "class")
table(predicted_tree, train\$income) # confusion matrix</pre>

Is there evidence of overfitting?

What is the overall accuracy?
What is Fensaturity?
What is Specificity?

Grerall accorning =
$$\frac{19669 + 1202}{19669 + 1202 + 63 + 5115}$$
 = 0.801
Sensetivity = $\frac{1202}{1202 + 5115}$ = 0.996
Specifity = $\frac{19669 + 63}{19669 + 63}$

Classification Trees - Picking the threshold value

- It tried all possible values c, such that $capital gain \le c$.
- \$5095 was the one the value that gave the "best" separation between >50K and <=50K.

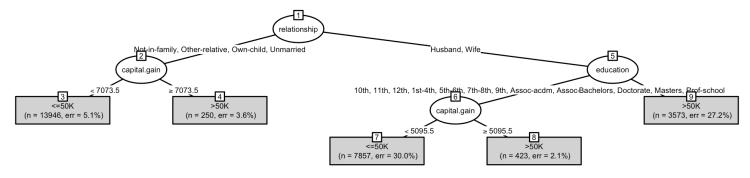

Classification Trees - Adding more variables

We have used only one variable to predict income, but we can use the other variables in the data to try and improve the accuracy.

Classification Trees - Adding more variables

```
form <- as.formula("income ~ age + workclass + education + marital.status + occupation +</pre>
                    relationship + race + sex + capital.gain + capital.loss + hours.per.week")
mod_tree <- rpart(form, data = train)</pre>
mod tree
                                      - built on training data.

               257 769
accuracy=0.85
```

Classification Tree Accuracy

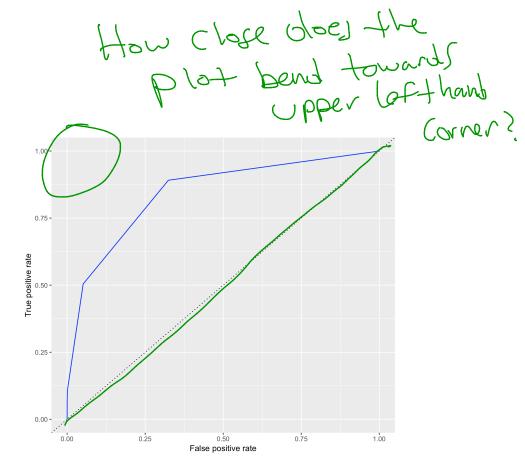

Since 24% of the sample earns >50K perhaps this is a more sensible cutoff for prediction.

The ROC curve is a plot of the true positive rate versus the false positive rate for various cut-points.

```
pred <- ROCR::prediction(predictions = predicted_tree[,2], test$income)
perf <- ROCR::performance(pred, 'tpr', 'fpr')
perf_df <- data.frame(perf@x.values, perf@y.values)
names(perf_df) <- c("fpr", "tpr")
roc <- ggplot(data = perf_df, aes(x = fpr, y = tpr)) +
geom_line(color = "blue") + geom_abline(intercept = 0, slope = 1, lty = 3) +
    ylab(perf@y.name) + xlab(perf@x.name)
roc</pre>
```

- The ROC curve is a plot of all possible threshold values for classification.
- The upper-left corner represents a perfect classifier, which would have a true positive rate of 1 and a false positive rate of 0.
- A random classifier would lie along the diagonal, since it would be equally likely to make either kind of mistake.

The true positive rate and false positive rate for a tree classifier with cutpoint 0.5.

```
predicted_tree <- predict(object = mod_tree, newdata = test, type = "prob")
m <- table(predicted_tree[,2] >= 0.50,test$income)
row.names(m) <- c("Pred <50K", "Pred >=50K")
tpr_50 <- m[4]/sum(m[,2])
fpr_50 <- m[2]/sum(m[,1])
tpr_50

## [1] 0.5045932

## [1] 0.05152366</pre>
```

The true positive rate and false positive rate for a tree classifier with cutpoint 0.24.

```
predicted_tree <- predict(object = mod_tree, newdata = test, type = "prob")
m <- table(predicted_tree[,2] >= 0.24,test$income)
row.names(m) <- c("Pred <50K", "Pred >=50K")
tpr_24 <- m[4]/sum(m[,2])
fpr_24 <- m[2]/sum(m[,1])
tpr_24

## [1] 0.8910761

## [1] 0.3243785</pre>
```

The tree with a cutpoint of 0.5 is shown as the black dot and the tree with a cutpoint of 0.24 is shown as the red dot.
